## Summaries

### Abstract (English):

The Two Higgs Doublet Model is a promising extension of the Standard Model where charged Higgs bosons appear. In this study, the mass of the charged Higgs boson is assumed to be 350 GeV. A simulation study is performed for the production and decay of charged Higgs boson pairs at a linear  $e^+e^-$  collider. A charged Higgs boson is assumed to decay to a top quark and a bottom quark followed by the top quark decaying into a bottom quark and a W boson. The event is reconstructed in two modes: First, both W bosons decay hadronically resulting in a total of eight jets and second, one W boson decays leptonically and the other W boson decays hadronically resulting in six jets, one lepton and missing momentum. The study is based on a full ILD simulation for collision energy of 1 TeV in expected ILC conditions.

The event selection is conducted with static cuts as well as boosted decision trees. Both methods are optimized on signal significance or on the significance for well reconstructed signal events. The mass measurement is undertaken with a template fit as well as with shape fitting methods. It is shown that the charged Higgs boson masses can be measured with 0.5 GeV precision assuming the production cross section 9 fb and a  $BR(H^\pm \rightarrow tb)$  of 90 %, when using boosted decision trees based event selection, optimized for well reconstructed signal significance with a parameter reduced shape fitting method for the mass measurement.

### Kurzfassung (German):

Modelle mit zwei Higgs-Dubletts sind aussichtsreiche Erweiterungen des Standard Models. In diesen Modellen treten geladene Higgs-Bosonen auf. In dieser Arbeit wird angenommen, dass die Masse dieser Higgs-Bosonen 350 GeV ist. Es wird eine Simulationsstudie der Produktion sowie des Zerfalls der geladenen Higgs-Bosonen an einem  $e^+e^-$ -Linearbeschleuniger durchgeführt. Es wird angenommen, dass ein geladenes Higgs-Boson in ein Bottom- und ein Top-Quark zerfällt, wobei das Top wiederum in ein Bottom und ein W-Boson übergeht. Der Prozess wird in zwei Moden rekonstruiert: Erstens beide W-Bosonen zerfallen hadronisch (resultierend in acht Jets) und zweitens ein W-boson zerfällt hadronisch und das andere zerfällt leptonisch (rekonstruiert durch sechs Jets, ein Lepton und Impulserhaltung). Die Studie basiert auf einer vollen ILD Simulation bei einer Kollisionsenergie von 1 TeV des International Linear Collider. Die Eventauswahl wird durchgeführt mit statischen Schnitten, sowie mit Boosted Decision Trees. Beide Methoden werden durch Maximierung der Signalsignifikanz oder der Signifikanz des gut rekonstruieren Signals trainiert. Die Massenbestimmung wird mit einer Template-Fit-Methode und Funktions-Fit-Methoden durchgeführt. Es wird gezeigt, dass die geladene Higgs Bosonen-Masse mit einer Präzision von 0.5 GeV bestimmt werden kann, wenn eine Parameter reduzierte Funktions-Fit-Methode mit Boosted Decision Trees basierter Eventauswahl optimiert für gut rekonstruiertes Signal benutzt wird. Hierbei wird angenommen, dass der Wirkungsquerschnitt 9 fb und das Verzweigungsverhältnis ( $BR(H^\pm \rightarrow tb)$ ) von 90 % sind.

*Dedication:*

*I am very grateful to Professor Hitoshi Yamamoto for making this work possible. I also want to thank Professor Arno Straessner for mentoring my master's study. The simulation was conducted by Junping Tian PhD (University of Tokyo) and provided for this study. I am very thankful to Junping Tian PhD, Mila Pandurovic PhD, Assistant Professor Ryo Yonamine, Jonas Wilzewski, Sophie Koßagk, Shun Watanuki, Yo Sato, Yuichi Okugawa and my whole laboratory for their support. Last but not least I am much obliged to my parents, Sayaka Chida and Sophia Neises for their contentious support.*

# 1 Introduction

## 1.1 Motivation

As long as we can look back in history, mankind was wondering how the world as we know began and where we came from. Since scientific thinking has evolved the scientific world postulates theories and tries to prove them in experiments. Today we still cannot be sure how the universe began. In order to satisfy this thirst for knowledge, we use particle colliders to investigate our models for higher energies because the earliest universe appeared in very high energy density. That is why the higher the studied energies are, the earlier universe we can learn about. Nowadays the most advanced particle collider is the Large Hadron Collider (LHC). With the discovery of a Higgs boson in July 2012 by the ATLAS and CMS detectors at the LHC, the Standard Model of particle physics (SM) was apparently completed and the long awaited puzzle piece of electroweak symmetry breaking was provided [1][2].

The SM is very promising and describes a wide ranges of particle physics' nature. But still there are many open questions in today's particle physics, such as baryon asymmetry, the hierarchy problem and the unknown nature of dark matter and dark energy, which cannot be answered by the SM. This makes one believe that there must be an extension of the SM (physics beyond the Standard Model (BSM)). Nevertheless, the SM must be the limiting model of this more general model. Aside from many other possible models, there are various Two Higgs Doublet Models (2HDM), which have the opportunity to answer some of these questions. For instance, the CP-violation of the current SM cannot explain the baryon asymmetry. However, by introducing additional CP-violation with a 2HDM the baryon asymmetry problem can be solved [3].

This study focuses on the analysis of charged Higgs boson ( $H^\pm$ ) pair production and in particular the measurement of the charged Higgs boson mass  $m_{H^\pm}$ . The direct search at an electron positron collider through on-shell Higgs bosons by s-channel production is fairly model independent and gives a solid limit on BSM in contrast to a proton collider where most measurements are highly model dependent. However, the reach is limited by the collision energy which is lower than at the LHC.  $H^+H^-$  pair production is especially interesting because the coupling to photons is fixed, thus the production cross section has a lower limit.

Recent combined results from BaBar, Belle and LHCb experiments showed a deviation to the SM of about four standard deviations [4]. The combined data showed that the branching ratios

of B-mesons involving muons and tau leptons could be larger as expected. In the SM electron, muon and tau leptons only differ in flavor and mass. This is called lepton universality. A confirmation of the results obtained in [4] would point to BSM. Since an increase of the decay into heavier particles was observed, a possible explanation could be the existence of charged Higgs bosons.

## 1.2 Two Higgs Doublet Model

Two Higgs Doublet Models (2HDM) are possible extensions of the Standard Model with an additional Higgs doublet. In the SM the Higgs mechanism adds a scalar field  $\Phi$  to the Lagrangian in the following manner

$$\mathcal{L}_{\text{Higgs}} = (D_\nu \Phi)^\dagger (D^\nu \Phi) + V(\Phi) \quad \text{where } V(\Phi) = \mu^2 \Phi^\dagger \Phi + \lambda (\Phi^\dagger \Phi)^2$$

$V(\Phi)$  is denoted by Higgs potential and  $D_\nu$  is the covariant derivative. If  $\lambda > 0$  and  $\mu^2 < 0$ , spontaneous symmetry breaking occurs and the minimum of the potential realizes the vacuum expectation value as

$$\nu = \sqrt{\frac{-\mu^2}{\lambda}}$$

When absorbing three degrees of freedom into the longitudinal component of  $W^\pm$  and Z boson, the in general complex Higgs field doublet can be simplified to

$$\Phi = \begin{pmatrix} 0 \\ \nu + h \end{pmatrix}$$

where  $h$  is the excitation around the minimum, or in other words, the SM Higgs boson [5].

However, the choice of Higgs potential is arbitrary. The potential could have higher order in  $\Phi$ , additional multiplets etc. One of the most minimal extensions with new properties is a second doublet. Then the Higgs potential can be written as

$$\begin{aligned} V(\Phi_1, \Phi_2) = & \lambda_1 \left( \Phi_1^\dagger \Phi_1 - \frac{\nu_1^2}{2} \right)^2 + \lambda_2 \left( \Phi_2^\dagger \Phi_2 - \frac{\nu_2^2}{2} \right)^2 + \lambda_3 \left( \Phi_1^\dagger \Phi_1 + \Phi_2^\dagger \Phi_2 - \frac{\nu_1^2 + \nu_2^2}{2} \right)^2 \\ & + \lambda_4 \left[ (\Phi_1^\dagger \Phi_1)(\Phi_2^\dagger \Phi_2) - (\Phi_1^\dagger \Phi_2)(\Phi_2^\dagger \Phi_1) \right] + \lambda_5 \left( \text{Re } \Phi_1^\dagger \Phi_2 - \frac{\nu_1 \nu_2}{2} \right)^2 + \lambda_6 \left( \text{Im } \Phi_1^\dagger \Phi_2 \right)^2 \end{aligned}$$

where  $\nu_k$  are the new vacuum expectation values. The Higgs doublets can be expressed as

(after absorbing three degrees of freedom into  $W^\pm$  and Z boson)

$$\Phi_k = \frac{1}{\sqrt{2}} \begin{pmatrix} \sqrt{2}w_k^+ \\ \nu_k + h_k + iz_k \end{pmatrix}$$

Applying  $\Phi_k$  to the  $\lambda_4$ -term in  $V(\Phi_1, \Phi_2)$  reveals the mass mixing for the charged sector

$$V_{H^\pm} = \frac{\lambda_4}{2} \begin{pmatrix} w_1^+ & w_2^+ \end{pmatrix} \begin{pmatrix} \nu_2^2 & -\nu_1^2\nu_2^2 \\ -\nu_1^2\nu_2^2 & \nu_1^2 \end{pmatrix} \begin{pmatrix} w_1^- \\ w_2^- \end{pmatrix}$$

Through digitalization, a pair of massless Nambu-Goldstone bosons  $G^\pm$  and a pair of massive Higgs  $H^\pm$  are predicted.

$$\begin{pmatrix} G^\pm \\ H^\pm \end{pmatrix} = \begin{pmatrix} \cos \beta & \sin \beta \\ -\sin \beta & \cos \beta \end{pmatrix} \begin{pmatrix} w_1^\pm \\ w_2^\pm \end{pmatrix}$$

where  $\tan \beta$  is defined as the ratio of the vacuum expectation values ( $\nu_2/\nu_1$ ). From this the charged Higgs bosons mass can be calculated as,

$$m_{H^\pm} = \frac{\lambda_4}{2} \nu^2 = \frac{\lambda_4}{2} \sqrt{\nu_1^2 + \nu_2^2}$$

with  $\nu$  the SM vacuum expectation values [5][6].

There are four types of 2HDM which avoid tree-level Flavor changing neutral currents naturally. Models where  $\Phi_1$  is fermiphobic and only  $\Phi_2$  couples to fermions are referred to as type I. If  $\Phi_1$  couples to up-type quarks and  $\Phi_2$  to down type quarks and charged leptons, it is usually called type II. The Higgs sector in the Minimal Supersymmetric extension of the Standard Model (MSSM) is a type II 2HDM. If  $\Phi_1$  couples to down quarks and  $\Phi_2$  to up quarks and leptons, it is denoted as type IV or flipped. In type IV or lepton specific models,  $\Phi_1$  couples to all leptons and  $\Phi_2$  to all quarks [7].

This study focuses on the direct search of charged Higgs bosons with a mass  $m_{H^\pm} = 350$  GeV. This value was chosen because it will not be excluded for a range of 2HDMs by the High Luminosity LHC. At the same time it is well in the reach of the purposed International Linear Collider (ILC) at a center-of-mass energy of  $\sqrt{s} = 1$  TeV. It is planned to apply this analysis to higher energy as a benchmark process.

In general, MSSM was assumed. However, since the extended Higgs sector in most Supersymmetric models couples only to SM particles and a model is not explicitly chosen for Monte Carlo simulation, the results of this study can be applied to majority of models with extended Higgs sector. In MSSM at the decoupling limit<sup>1</sup> the coupling of charged

<sup>1</sup>The decoupling limit denotes the situation with large mass of the CP-odd Higgs boson ( $m_A \rightarrow \infty$  or in a different way  $m_A \gg m_Z$ )

Higgs bosons and gauge bosons are small and the coupling to fermions is dominant. Because the Yukawa couplings (Higgs couplings to fermions) are proportional to the mass of the fermions, the branching ratio of a charged Higgs boson with  $m_{H^\pm} > m_t + m_b$  to top and bottom quarks becomes dominant. In this study the branching ratio  $BR(H^+ \rightarrow t\bar{b}) = BR(H^- \rightarrow \bar{t}b) = 90\%$  was assumed. This leaves some space for decays to tau leptons or for smaller  $\tan\beta$  decays to  $hW$  as well. This has been chosen in consistency with [8] (see figure 1.1). The production cross section  $\sigma(e^-e^+ \rightarrow H^+H^-)$  is assumed to be 9 fb. This is based on figure 1.2 which was taken from [9] and was interpreted for the considered mass.

In the following, signal refers to  $e^-e^+ \rightarrow H^+H^-$  where  $H^\pm$  decays into  $b\bar{t}$  and  $\bar{b}t$  respectively. Both  $t$  decay to  $W b$ . If both resulting  $W$  bosons decay into quarks, it will be referred to as hadronic signal (see Figure 1.3). If one  $W \rightarrow \ell\nu_\ell$  ( $\ell = e, \mu$ ) and the other  $W \rightarrow q_u q_d$  ( $q_u = u, c$  and  $q_d = d, s, b$ ), it will be denoted by semi-leptonic signal.

**Figure 1.3:** Feynman diagram of signal (hadronic channel)

Current limits for charged Higgs bosons through direct search are from data of the Large Electron-Positron Collider (LEP). With CL 95% the limits  $m_{H^\pm} > 80$  GeV for type II 2HDMs and  $m_{H^\pm} > 72.5$  GeV for type I (from  $\tau\nu$  and  $cs$  final states) were found [10]. The collision energy of LEP was  $\sqrt{s} = 209$  GeV. The direct search for charged Higgs is limited by the accessible centre-of-mass energy, so translating this result naively to a linear collider with a  $\sqrt{s} = 1$  TeV, a limit up to 400 GeV should be easily reachable.

Latest combined constrains from various experiments on the charged Higgs mass in different models can be found in [7]. For a wide range of models and  $\tan\beta$  regions the tightest limit comes from the LEP search; in others models from flavor changing processes (typically for type II 2HDMs) the limit is around  $m_{H^\pm} \gtrsim 600$  GeV. This is because a light charged Higgs would have impact on flavor physics and various branching ratios of B mesons would be deviated. In some models and  $\tan\beta$  regions the limit is from direct searches at the LHC over 1 TeV. This leaves a wide range of models and parameter regions to exclude at a future electron positron collider. However, the MSSM with type II 2HDM is already excluded with a charged Higgs boson mass of 350 GeV (see [7]).

Nevertheless the study here, only the cross section was chosen in agreement of MSSM which makes the results applicable to other models. Moreover, the developed methods can be transferred to higher  $m_{H^\pm}$  at electron positron colliders with higher collision energy.

Since production cross-section [9] and the branching ratio [7] are, compared to the HA-channel, relatively independent from  $\tan\beta$ , the  $H^-H^+$ -channel was chosen to be analyzed in this study.

**Figure 1.1:** Branching ratios of the charged Higgs bosons in dependence of their mass for  $\tan \beta = 3$  (left) and  $\tan \beta = 30$  (right) (source: [8])

**Figure 1.2:** Tree-level and full one-loop corrected cross sections are shown for  $\sqrt{s} = 1$  TeV and  $\sqrt{s} = 800$  GeV with varied  $m_{H^\pm}$  (source: [9])

**Figure 1.4:** Constraints of  $(m_{H^\pm}, \tan \beta)$  parameter space of MSSM-like scenarios. The color coding corresponds to exclusion of 95 % C.L. by charged and neutral Higgs searches for the four different 2HDM types with different constraints, as given by the legend. The green region is allowed by all collider constraints. The dotted line frames the excluded area from flavor changing current observables, where the lower  $\tan \beta$  side is excluded (source: [7])

This is only true for the decoupling limit where  $BR(H^\pm \rightarrow hW^\pm)$  becomes small. In addition the  $H^-H^+$  production is interesting because  $\tan \beta$  can be determined by the decay width of  $H^\pm$  [11]. Furthermore, pair production in general is a "clean" event where only the  $H^\pm$  particles themselves are produced and there are no byproducts. This simplifies the analysis and enhances the mass measurement precision.

In addition, this channel has the opportunity to observe CP-violation in the Higgs sector through branching ratio asymmetry, which is a possible explanation of the baryon abundance in the universe as mentioned earlier. The CP-violation phase is defined as

$$\delta_{f\bar{f}}^{CP} = \frac{BR(H^+ \rightarrow f\bar{f}') - BR(H^- \rightarrow \bar{f}f')}{BR(H^+ \rightarrow f\bar{f}') + BR(H^- \rightarrow \bar{f}f')}$$

$\delta_{f\bar{f}}^{CP}$  depends in MSSM on various parameters [12]. It is accessible in the semi-leptonic mode with the lepton charge and in the leptonic mode where both W bosons decay to lepton and neutrino pair. In the hadronic decay it may be reconstructible through the charge of the bottom jets.

## 1.3 International Linear Collider and International Large Detector

**Figure 1.5:** Schematic representation of the ILC (source: [13])

The International Linear Collider (ILC) [13] (see figure 1.5) is a proposed electron positron collider with a tunable center-of-mass energy in the range of 250 GeV to 500 GeV and can be upgraded to reach up to 1 TeV. The ILC evolved out of three projects, the Japanese GLC, European TESLA-collider and American NLC, and is now supported by the worldwide particle physics community. The ILC is planned to be constructed in Iwate prefecture in northern Japan. In 2013 the technical design report was published which reports detailed about the accelerator, detector and physics outcome of the project ([13][14][15][16][17]). At the ILC, in comparison to a proton collider such as the LHC, one needs fewer model assumptions, there is fewer background and the initial state is well known. It is even possible to polarize 80 % of the electron beam and 30 % of the positron beam. At a collision energy of 1 TeV the positron polarization is expected to lower to 20 %.

To ensure a cross check of the measurement, the ILC will have two detectors, the International Large Detector (ILD) and the Silicon Detector (SiD), which will share the same interaction region by push-pull technique. In this analysis only the ILD is considered. It consists of a high-precision vertex detector surrounded by a hybrid tracking system with a silicon tracker and time-projection chamber. For optimal particle-flow performance a highly granular electromagnetic and hadron calorimeter system was developed. The whole detector barrel is contained in a 3.5 T solenoid [13].

The exact operation plan of the ILC will be decided from funding and discoveries in particle physics. The collision energy is relatively easy to adjust, so that depending on discoveries of the LHC at CERN or other experiments the energy can be adjusted. A possible running scenario could be

- 91 GeV: Z boson peak for calibration and precise measurements of Z properties
- 160 GeV:  $W^\pm$  pair production for precise measurements of W properties

- 250 GeV: Higgs factory through Higgs-Strahlung
- 350 GeV: Top quark factory through pair production
- 500 GeV: Top Yukawa coupling, BSM search, fermion pair production and Higgs through W-fusion
- 1 TeV: BSM search

This should not be an exclusive list but rather a quick overview on interesting physics accessible at a linear electron positron collider. 1 TeV as center mass energy is rather arbitrary but would give a new view on otherwise not accessible energy regions and gives a first mark on where to look at.

The accelerator of the ILC will be based on 1.3 GHz superconducting radio-frequency accelerating technology. The initial ILC will have a length of 31 *km* which can be extended to 50 *km*. With this length the ILC can reach 1 TeV or more. In the TDR a scenario A was proposed for 1 TeV [13] the luminosity is expected to be  $L = 3.6 \cdot 10^{34} \text{ cm}^{-2} \text{ s}^{-1}$ . In this analysis the integrated luminosity is assumed to be  $\mathcal{L} = 1 \text{ ab}^{-1}$ . This accounts for 324 days of running. Which calls for about three years of running at  $\sqrt{s} = 1 \text{ TeV}$  considering service time.

## 1.4 Simulation and Reconstruction

In this study Monte Carlo data samples generated by Physsim and Whizard are analyzed. The signal of charged Higgs pair production is generated by Physsim [18] which is based on HELAS [19] for matrix element calculation. The SM background was generated by Wizard 1.95 [20]. Parton shower and hadronization was performed by Pythia 6.4 [21]. The beam spectrum is simulated by GuineaPig [22] and is incorporated in both the signal and background generators. In addition to the main event all data samples are overlaid with in average 4.1 events of  $\gamma\gamma$  to hadron events with low transversal moment. This type of beam-induced background will be addressed further in chapter 2.3.1. The detector was simulated with Mokka [23] on a full ILD model (ILD\_o1\_v05) based on the Detailed Baseline Design (DBD) [17]. For reconstruction the Pandora Particle Flow Algorithm [24] (PandoraPFA) was used. PandoraPFA uses the tracking information combined with calorimeter information to reconstruct individual particles in order to improve energy and momentum resolution. This improves the jet resolution and allows better separation of the W, Z, H bosons and top quark by their invariant mass [24].

In the frame of this study the FastJetFinder [25] was used for beam-induced background reduction, LCFIplus [26] package was used for vertex reconstruction and flavor tagging. A dedicated Marlin [27] processor was written for this analysis. The output of the analyzer was stored to

ROOT-files [28]. After the event by event analysis with Marlin, ROOT 6.08 accessed with pyroot [28] was then used for final analysis.

For computing, the KEK Central Computer System [29] was used.

As background, only SM processes including various SM-like Higgs events in all final states are considered. Beam photon interactions, which include  $\gamma\gamma$ -annihilation and interactions with beam electrons or positrons were considered as well. A detailed list of all used data samples can be found in Table A.1.

# 2 Data Analysis

## 2.1 Analysis Strategy

All data samples used in this study are scaled to an integrated luminosity of  $\mathcal{L} = 1 \text{ ab}^{-1}$ . The polarization of both beams are included as  $P(e^-, e^+) = (-80\%, 20\%)$  [13]. The samples used in this analysis had two polarizations,  $P_L = (-100\%, 100\%)$  and  $P_R = (100\%, -100\%)$ . Weights are assigned to obtain samples of correct polarization. If the required polarization is  $P(e^-, e^+) = (-f^-, f^+)$ , then the weights are

$$w_{L,i} = \left[ f^- + \frac{1}{2}(1 - f^-) \right] \left[ f^+ + \frac{1}{2}(1 - f^+) \right] \frac{\mathcal{L}\sigma_i}{N_{i,\text{sim}}} \text{ and } w_{R,i} = \left[ \frac{1}{2}(1 - f^-) \right] \left[ \frac{1}{2}(1 - f^+) \right] \frac{\mathcal{L}\sigma_i}{N_{i,\text{sim}}}$$

where  $w_{L,i}$  stands for the weight of the data sample of process  $i$  where the electron is left handed and positron is right handed.  $w_{R,i}$  is the weight for samples with opposite polarization,  $N_{i,\text{sim}}$  is the number of simulated events and  $\sigma_i$  is the corresponding cross section. Therefore the weights used here are

$$w_{L,i} = 0.9 \cdot 0.6 \cdot \frac{\mathcal{L}\sigma_i}{N_{i,\text{sim}}} \text{ and } w_{R,i} = 0.1 \cdot 0.4 \cdot \frac{\mathcal{L}\sigma_i}{N_{i,\text{sim}}}$$

Processes with other polarization are weighted in an analogous manner. A full list of all samples with responding weights, cross section, expected number of events and generated number of events can be found in table A.1.

A flow diagram of processors for the event by event based analysis by Marlin is shown in figure 2.1. For the hadronic mode the kt-algorithm with requesting eight jets (FastJet\_kt\_8) is used to reduce beam background (chapter 2.3.1), while for the semi-leptonic mode one lepton is removed (chapter 2.2) before kt-algorithm with requesting six jets (FastJet\_kt\_6) is used. The clustered event gets restored into tracks in an intermediate step (JetPFOs). Then the vertex reconstruction (VertexFinder), final jet clustering and b-tagging (JetClustering And FlavorTag) are done (chapter 2.3.2). Finally all relevant collections are analyzed and relevant observables are saved into a ROOT-file (h2dmAnalysis).

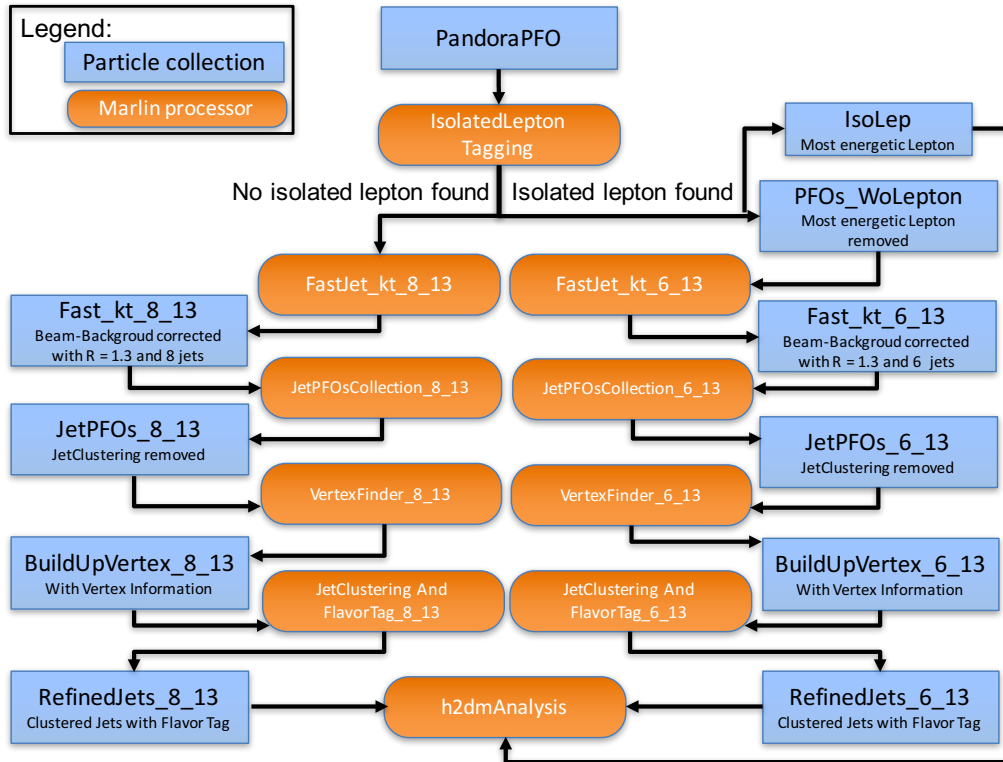

Figure 2.1: Schematic diagram of Marlin processor structure

## 2.2 Lepton selection

For the lepton selection, the `IsolatedLeptonTaggingProcessor` [30] is included in the `MarlinReco` package [27] since version `v01-12`. This processor uses a neural network (multilayer perceptron) of the `TMVA` package (Toolkit for Multivariate Data Analysis [31] integrated in `ROOT`) to select one isolated lepton. Here weights<sup>1</sup> trained on four fermion processes at  $\sqrt{s} = 500$  GeV because there are no weights trained on  $\sqrt{s} = 1$  TeV available. Nevertheless, the tagging efficiency is around 90 % on a high level (for details see table 2.1).

It is important to select the isolated lepton before the beam background reduction (chapter 2.3.1) because the used kt-algorithm requires six jets and removes particles which are far from those jets. So isolated leptons will be removed in some events. On the other hand it is very unlikely to select a particle of the beam background as the isolated lepton. The lower efficiencies for the isolated lepton selection in table 2.2 is proving this.

In 2 % of the hadronic signal an isolated lepton is mistakenly selected. The reason for, this unexpected large ratio, maybe the weights trained on  $\sqrt{s} = 500$  GeV because with larger energy in the event leptons in the jets have larger energy and might be selected mistakenly.

<sup>1</sup>weights\_isolated\_electron\_llh\_gg\_bbbb\_500 and weights\_isolated\_muon\_llh\_gg\_bbbb\_500 located at `/home/ilc/tianjp/analysis/PostDBD/IsolatedLeptonTagging/weights/`

	correct lepton selected	other particle selected

	correct lepton selected	other particle selected
e	86.9	0.6
$\mu$	88	0.45
$\tau$	8.2	1.8

**Table 2.2:** Table of isolated lepton selection efficiencies; all numbers are given in percent, e stands for the semi-leptonic signal where  $W \rightarrow e\nu_e$ ;  $\tau$  and  $\mu$  have analogous mining (beam background removal is done before isolated lepton selection)

## 2.3 Jet Reconstruction

### 2.3.1 Hadronic Beam-Induced-Background

The particle beams are bent under the electro-magnetic field of the opposite beam and thus radiate photons. This is referred to as beamstrahlung. In general these photons can react to produce  $e^+e^-$  pairs, most of which are very close to the beam line and will not get detected by the main detector but those are problematic in terms of radiation damage for materials and apparatuses in forward region.

In order to increase the luminosity at linear colliders, a great effort has to be made to focus the beams into a very small transverse size to collide. Thus the approaching beams are exposed to very large electro-magnetic field of the opposite bunch. The bunches are attracted to the center of the oncoming bunches with opposite charge and get focused even stronger which increases the luminosity. This is called pinch effect. Through relativistic effects, the pinch effect becomes stronger with higher energy, which boosts luminosity and at the same time beamstrahlung as well.

The photons from beamstrahlung produce quark pairs as well which effects this analysis and has a large impact on the resolution because of their high energy. On average, 4.1 of these events were expected per bunch crossing for ILC at 1 TeV but a new study suggests a lower rate of 2.7 [32]. Nevertheless, an average of 4.1 events were overlaid to the data samples used here.

These quark pairs, hadronising to various hadrons, are reduced with the kt-algorithm of the FastJetFinder ([25], [33]). This method was adapted from similar studies (e.g. [34]).

Generally speaking, the kt-algorithm clusters all tracks to a requested number of jets. If a track is closer to the beam line than to the closest jet, the track gets removed. In order to

calculate the distance to the jet, a generalized Radius  $R$  is used. This  $R$  value is used to optimize how many particles get removed.

In detail, the kt-algorithm follows this steps:

1. Calculate the distance between all tracks

$$d_{ij} = \min(p_{Ti}^2, p_{Tj}^2) \frac{\Delta R_{ij}}{R}$$

where  $\Delta R_{ij} = (\eta_i - \eta_j)^2 + (\phi_i - \phi_j)^2$ ,  $\eta$  is the pseudo rapidity and  $\phi$  the azimuth (angle perpendicular to beam pipe) and  $p_{Ti}$  is the transverse momentum of track  $i$ .

2. Find the smallest  $d_{ij}$

- a) If  $d_{ij} < d_{iB} = p_{Ti}^2$ , merge tracks

- b) If not, remove Track  $i$

( $d_{iB}$  is the distance between track  $i$  and beam line)

3. Continue with the first step until there are only  $N$  tracks, where  $N$  is the number of requested jets [25]

The value of  $R$  was varied in the range of 0.1 to 1.5. Then the clustered event gets restored to tracks and reclustered by the Durham algorithm [35] accessed through SatoruJetFinder from the MarlinReco package [27]. The SatoruJetFinder was used rather than the LCFIplus [26] because the computing time of LCFIplus is much longer but the clustering result is similar to the Durham algorithm.

To estimate which  $R$  values is appropriate for this study, the mass of both charged Higgs bosons is calculated. In order to do so, one of the four color singlets<sup>2</sup> are connected to each jet as following: the color singlet which gave the largest contribution to the jet in terms of energy is assigned. This is done with generator information and cannot be known in the real experiment.

Now the events are classified to three categories:

- a) If all four color singlets have each two jets assigned, the assignment is final (good clustering)<sup>3</sup>
- b) If color singlet  $k$  has only one jet assigned and color singlet  $j$  has three jets assigned, the jet with highest  $\frac{E_{k,i} - E_{j,i}}{E_{k,i} + E_{j,i}}$  is reassigned to color singlet  $k$  (moderate clustering) where  $E_{l,i}$  denotes the energy of jet  $i$  resulting from color singlet  $l$

---

<sup>2</sup>The color singlets in this process the color singlets develop as follows:

$$H^+ H^- \rightarrow \langle \bar{b}t \rangle \langle W^+ \rightarrow q\bar{q} \rangle \langle \bar{b}t \rangle \langle W^- \rightarrow q\bar{q} \rangle$$

where each color singlet is marked with  $\langle \rangle$

<sup>3</sup>occurrence is shown in table 2.3

c) In other cases the event gets discarded for this calculation (failed clustering)

Since it is known which color singlet originated from which charged Higgs through generator information,  $m_{H^+}$  can be defined as the invariant mass of the jets assigned to the two color singlets from  $H^+$ . The invariant mass of the other four jets is  $m_{H^-}$ . The relation between color singlet and jet stays unknown for events with failed clustering and the masses cannot be reconstructed. Therefore, these events are discarded for this chapter.

**Figure 2.2:** Charged Higgs mass (right:  $m_{H^+}$ , left:  $m_{H^-}$ ) in green  $\gamma\gamma$ -background removed by generator in formation, black without any correction and other colors with corrected with kt-algorithm with varied  $R$  as noted in the legend (see figure A.1 for more values for  $R$ )

As one can see in figure 2.2 the contribution of the  $\gamma\gamma$ -background to the reconstructed Higgs mass can be reduced with the used kt-algorithm. If the generalized radius  $R$  is chosen too small, tracks from the real event tend to get removed. Thus some energy in the event is removed and the reconstructed Higgs mass becomes smaller. Values between 1 and 1.3 for  $R$  were found to be appropriated. In order to avoid removing tracks of the real event a relatively high value of  $R = 1.3$  was chosen. This is consistent with an earlier study of the top-Yukawa-coupling at 1 TeV where the same final state was analyzed where  $R = 1.2$  was chosen [34]. The influence of the background removal on jet pairing, b-tagging and clustering is shown in table 2.3. Jet pairing, b-tagging and clustering will be treated in the next chapters (2.3.3 and 2.3.2)

The background removal with kt-algorithm was only studied on hadronic signal. Nevertheless, the  $\gamma\gamma$ -background is corrected as well for semi-leptonic background in the same manner. After the lepton selection the kt-algorithm runs on the rest of the event while requesting six jets and setting  $R = 1.3$ .

### 2.3.2 Jet Clustering

The LCFIplus package [26] is used for the final jet clustering. LCFIplus uses the LCFIVertex package [36] and improves the clustering utilizing vertex information. At the same time LCFIplus provides a bottom quark likeliness called b-tag for every requested jet. The b-tagging is done with boosted decision trees of the TMVA package and is essential in this study for the jet pairing and event selection (chapter 2.3.3 and 2.5). LCFIplus is using pretrained weights to calculate the b-tag values. Here the 6q1000\_v02\_p01 was used, which has been trained on events with six jet at  $\sqrt{s} = 1$  TeV, however they are used for both hadronic and semi-leptonic mode because of the lack of weights trained on eight jet events.

### 2.3.3 Jet pairing

The jet pairing is performed with a chi square minimization. The  $\chi^2$  is defined as

$$\chi^2 = \left| \frac{(m_{j_1 j_2 j_3 j_4})^2 - (m_{j_5 j_6 j_7 j_8})^2}{2\sigma_{H^\pm}^2} \right| + \left( \frac{m_{j_2 j_3 j_4} - m_t}{\sigma_t} \right)^2 + \left( \frac{m_{j_6 j_7 j_8} - m_t}{\sigma_t} \right)^2 + \left( \frac{m_{j_3 j_4} - m_W}{\sigma_W} \right)^2 + \left( \frac{m_{j_7 j_8} - m_W}{\sigma_W} \right)^2 \quad (2.1)$$

where  $j_1, j_2, j_5$  and  $j_6$  are b-jets and  $j_3, j_4, j_7$  and  $j_8$  are light jets from W decays.  $\sigma_{H^\pm}$  and  $\sigma_t$  have been chosen to 80 GeV and  $\sigma_W$  to 48 GeV. These values are taken from the width of the relevant mass distributions with the described jet pairing method in chapter 2.3.1 using generator information. In the first term of  $\chi^2$  for the Higgs mass, the difference of the two masses were introduced, rather than the deviation to the expected mass in order not be biased towards the expected mass.

The total combinations of the eight jets are  $N = 8! = 40320$ . In order to obtain better quality of the jet pairing and reduce the number of possible jet pairing combinations, the following conditions are applied:

- The four jets with highest b-tag are required to be the jets from bottom quarks. This reduces the combination to  $N = 4!^2 = 576$ .
- Without exchanging the jets from a given W boson and without exchanging the two Higgs bosons with each other. Therefore, the combinations reduce to  $N = \frac{4!^2}{2^4} = 36$ .

With this reduced number of options the computing time is unproblematic and furthermore, the risk of getting a small  $\chi^2$  for a wrong combination is low.

From the method explained in chapter 2.3.1 the underlying color singlet of the jets is known and can be compared to the  $\chi^2$  pairing. If the pairing agrees, it will be called correctly paired. About one quarter of the hadronic signal is correctly paired (see table 2.3).

	Uncorrected <sup>†</sup>	$R = 1.3^{\dagger\dagger}$	no $\gamma\gamma$ -BG <sup>†††</sup>	Description
b-tag	38.0 %	42.5 %	44.6 %	The four b-jets have highest b-tag in the event
good clustering	40.2 %	49.5 %	50.7 %	As defined in chapter 2.3.1
working clustering	92.5 %	95.6 %	95.8 %	Good and moderate clustering from chapter 2.3.1
correctly paired	17.2 %	24.5 %	27.8 %	Jet pairing agrees with major color singlet fraction in jet

<sup>†</sup> Without any correction

<sup>††</sup> Beam background corrected with kt-algorithm with  $R = 1.3$

<sup>†††</sup> Overlay removed with generator information

**Table 2.3:** Table of clustering, b-tagging and pairing efficiencies

In the case of semi-leptonic signal, the same  $\chi^2$  pairing is used but the jets  $j_7$  and  $j_8$  are required to be the lepton four momentum and the neutrino four momentum respectively. The reconstruction of the neutrino will be treated in chapter 2.4.

Despite the very high b-tagging efficiency, there are still a number of events with low b-tag values. For most of these events the clustering rather than pairing or b-tagging is problematic. Before, two categories (b-jets and light jets) were defined. However, for these events with bad clustering, a more realistic pairing can be reached, if the following three categories are defined:

1. b-jets (with highest b-tag)
2. light jets (lowest b-tag)
3. unknown flavor jets (with medium b-tag)

Here the combinations are with two jets in the third category  $N = \frac{8*7*3!^2}{2^4} = 126$  or with four jets in the third category  $N = \frac{8*7*6*5*2!^2}{2^4} = \frac{8!*2^2}{4!*2^4} = 420$ .

This method becomes effective for events with low b-tag but those events will be rejected by the background suppression (chapter 2.5) later on and has therefore no effect on the final result.

Another method to improve the jet pairing is the optimization of  $\chi^2$  or adding other terms. Therefore the following  $\chi_{\text{optim}}^2$  with weight  $w$ , which will be optimized, was tested

$$\begin{aligned}
\chi_{\text{optim}}^2 = & w_H \left| \frac{(m_{j_1 j_2 j_3 j_4})^2 - (m_{j_5 j_6 j_7 j_8})^2}{2\sigma_{H^\pm}^2} \right| + w_t \left( \frac{m_{j_2 j_3 j_4} - m_t}{\sigma_t} \right)^2 + w_t \left( \frac{m_{j_6 j_7 j_8} - m_t}{\sigma_t} \right)^2 \\
& + w_W \left( \frac{m_{j_3 j_4} - m_W}{\sigma_W} \right)^2 + w_W \left( \frac{m_{j_7 j_8} - m_W}{\sigma_W} \right)^2 + w_\theta \left( \frac{\theta_{H^+ H^-} - \pi}{\sigma_\theta} \right)^2 \\
& + w_{\cos} \left( \frac{1 - \cos \theta_{H^+ H^-}}{\sigma_{\cos}} \right)^2 + w_E \left( \frac{E_{H_1} - E_{H_2}}{\sigma_E} \right)^2
\end{aligned}$$

with

$$E_{H_1} = \sum_{i=1}^4 E_i \quad \text{and} \quad E_{H_2} = \sum_{i=5}^8 E_i$$

where  $E_i$  is the energy of jet  $i$ .  $\theta_{H^+H^-}$  is the production angle between the charged Higgs bosons formed by the reconstructed jets. The different widths were chosen to

$$\sigma_\theta = 0.3, \quad \sigma_{\cos} = 0.18, \quad \sigma_E = 117 \text{ GeV}$$

with the same method as mentioned before.

By optimizing two of the weights at the same time, the following optimal choice was found:

$w_H$	$w_W$	$w_t$	$w_\theta$	$w_{\cos}$	$w_E$
1	2	3	0.6	0	0

This improves the pairing efficiency by about 1.6 % from 24.5 % to 26.1 %. The effect of this on the final result was not checked because of lack of the time but the effect is expected to be small because the improvement is small. This was again only studied for hadronic signal.

In order to check jet clustering and pairing, a 3D-display was developed for visual inspection on an event by event bases. An event, where two jets got clustered to one and another jet got split into two, is shown in figure 2.3. This kind of events are common but in most events with bad clustering it is difficult to figure out what is going on because of the large number of jets.

**Figure 2.3:** 3D-display to check jet clustering and pairing event by event. In the running program the upper left quarter can be turned with the mouse. The other quarters show the projection on one plane as noted. The dashed lines are displayed from simulator information and the solid lines show the reconstructed jets. Here the display shows an event where two jets got clustered to one and another jet got split into two. The ovals are added to indicate the issue.

## 2.4 Neutrino Reconstruction

In the case of semi-leptonic signal one neutrino has to be reconstructed. Therefore, four methods were tested. Since the neutrino cannot be detected its four momentum has to be calculated from the missing momentum and energy in the event. The largest uncertainties for this is the beam spectrum, missing momentum from other neutrinos in the jets, beam background and beam background reduction.

### 2.4.1 Missing Energy Method (MEM)

The idea in MEM is simply using total four momentum of the event  $p_{\text{vis}}$  and subtract it from the momentum of the center of the mass system (CMS)  $p_{\text{CMS}}$ . Because the crossing angle will be 14 mrad and the collision energy 1 TeV[13], it is given as

$$p_{\text{CMS}} = (1 \text{ TeV}, 0, 0, 1 \text{ TeV} \cdot \sin(0.014/2))$$

$p_{\text{vis}}$  is simply the sum over all Particle Flow Objects (PFO) which are the tracks

$$p_{\text{vis}} = \sum_{i=1}^{N_{\text{PFO}}} p_i$$

Thus the neutrino four momentum can be written as

$$p_{\nu,\text{MEM}} = p_{\text{CMS}} - p_{\text{vis}} \quad (2.2)$$

This method is typically used for ILC analysis.

### 2.4.2 Missing Momentum Method (MMM)

This is a slight modification of MEM. Because the momentum resolution is better than the energy resolution (see figure 2.4) and the neutrino mass is negligible, the relation  $E = p$  is adopted. Therefore, the neutrino four momentum can be written as

$$p_{\nu,\text{MMM}} = (|\vec{p}_{\nu,\text{MEM}}|, \vec{p}_{\nu,\text{MEM}})$$

**Figure 2.4:** Relative deviation of generated and reconstructed  $\frac{k_{\text{reco}} - k_{\text{gen}}}{k_{\text{gen}}}$  where  $k$  is  $|\vec{p}|$  (absolute momentum),  $p_i$  (momentum components) or  $E$  (energy) of the neutrino as noted in the legend determined by MEM

### 2.4.3 Missing Direction Method (MDM)

The invariant mass of the neutrino-lepton system is the W boson mass. This information can be used to improve the resolution. Because the resolution of the direction of missing momentum is better than the energy resolution, the reasoning of the MDM is to calculate the neutrino Energy  $E_\nu$  from the mass constraint (compare figure 2.4).

The W mass can be written as

$$m_W^2 = (p_\nu + p_\ell)^2 = p_\nu^2 + 2p_\nu p_\ell + p_\ell^2 = 2p_\nu p_\ell$$

where  $p_\nu$  and  $p_\ell$  denote the four momenta of neutrino and lepton respectively. The assumption  $p_\nu^2 = p_\ell^2 = 0$  was used, which is obvious for neutrinos and reasonable for leptons, since muon and electron momentum are much larger than the mass.

Simplifying farther:

$$m_W^2 = 2(E_\nu E_\ell - \vec{p}_\nu \vec{p}_\ell) = 2E_\nu E_\ell (1 - \cos \theta) \quad (2.3)$$

the assumption of negligible mass was applied again in from of  $E_i = |\vec{p}_i|$  and  $\cos \theta$  is the decay angle of neutrino and lepton

$$\cos \theta = \frac{\vec{p}_{\nu, \text{MEM}} \cdot \vec{p}_\ell}{|\vec{p}_{\nu, \text{MEM}}| |\vec{p}_\ell|}$$

solving this for  $E_\nu$  gives the estimate of this method for the neutrino energy as

$$E_{\nu, \text{MDM}} = \frac{m_W^2}{2E_\ell (1 - \cos \theta)}$$

and the four momentum as

$$p_{\nu, \text{MDM}} = \left( E_{\nu, \text{MDM}}, E_{\nu, \text{MDM}} \frac{\vec{p}_{\nu, \text{MEM}}}{|\vec{p}_{\nu, \text{MEM}}|} \right)$$

An additional uncertainty of this method comes from the W width but is small in comparison to the uncertainty on the direction of missing momentum.

## 2.4.4 Missing Transversal Momentum Method (MTMM)

In this method the idea is to use only the missing momentum of the event in transversal direction orthogonal to the beam pipe. Looking at figure 2.4 it is obvious that the resolution of the transversal direction is better than in  $z$ -direction for a number of reasons.

- **Beam background:** As discussed in chapter 2.3.1, beam background is mainly in forward direction as well as the beam background reduction, discussed in the same chapter. Remaining beam background or removed tracks from the main event contribute largely to the resolution in  $z$ -direction.
- **Beam spectrum:** The variance in the  $z$ -component of the beam electron and positron are much larger than it is in transverse components.

- **Undetected particles:** Particles of the main event can in general get lost in the beam pipe. Furthermore, the detectors in the barrel have a better accuracy than in the end caps.

Equation 2.3 is reused as follows

$$\frac{m_W^2}{2} = E_\nu E_\ell - \vec{p}_\nu \vec{p}_\ell = E_\ell \sqrt{p_{\nu x}^2 + p_{\nu y}^2 + p_{\nu z}^2} - p_{\nu x} p_{\ell x} - p_{\nu y} p_{\ell y} - p_{\nu z} p_{\ell z}$$

where  $p_{pi}^2$  donates the component  $i$  of  $p$ 's momentum.

This is a fairly complicated second degree polynomial. Nevertheless, it can be solved with the quadratic formula for the neutrino momentum in  $z$ -direction  $p_{\nu z}$ . The solution was found to be

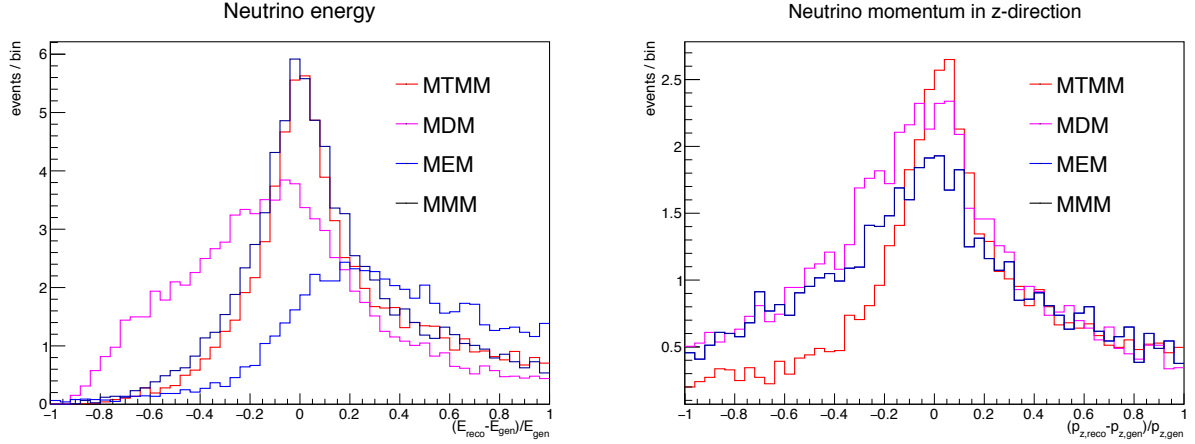

$$p_{\nu z} = \frac{\pm K + p_{\ell z} [2(p_{\ell y} p_{\nu y} + p_{\ell x} p_{\nu x}) + m_W^2]}{2(p_{\ell x}^2 + p_{\ell y}^2)}$$

with

$$K = E_\ell \sqrt{4[(2p_{\ell x} p_{\nu x} + m_W^2)p_{\ell y} p_{\nu y} - p_{\ell x}^2 p_{\nu y}^2 - p_{\ell y}^2 p_{\nu x}^2 + m_W^2 p_{\ell x} p_{\nu x}] + m_W^4}$$

It has two solutions. In this study the solutions closer to the  $z$ -component of MEM  $p_{\nu, \text{MEM}z}$  is selected. Theoretically the square root of  $K$  cannot become imaginary but from uncertainties there are cases where it would become imaginary. In order to prevent that the absolute value is used.

In figure 2.5 the energy deviation and deviation in  $z$ -component of the momentum to the generated value is shown for the methods explained. When comparing the methods MTMM is the best in the momentum but in the energy deviation MMM is a little better. Very badly reconstructed events can have a very large deviation from the real value for MTMM and MDM because of error evolution. However, MEM and MMM are stable for even those events. Since MEM and MMM have the exact same momentum but because MMM is much better for the energy reconstruction, it was chosen for the further analysis. Furthermore, MMM does not fix the  $W$  mass and leaves the opportunity to use this value for the further analysis. Nevertheless, MTMM could be a good alternative for most events.

**Figure 2.5:** Comparison of the four methods for neutrino reconstruction; right figure shows deviation between reconstructed and generated energy; left figure shows the deviation for the  $z$ -component of the momentum

## 2.5 Event Selection

The event selection is optimized for maximal significance which is defined as

$$S = \frac{N_S}{\sqrt{N_S + N_B}}$$

where  $N_S$  is the number of signal events and  $N_B$  the total number of background events. In a simple counting experiment, the statistical uncertainty would be the inverse of the significance.

$$\frac{\Delta N}{N} = \frac{1}{S}$$

One can optimize the event selection on the signal significance or on the correctly paired signal significance using the definition of correct pairing from chapter 2.3.3. In this study both has been tried out. In the case of optimization for correct pairing other signal was not added to  $N_B$ . Beside that hadronic signal was not considered as background when optimizing semi-leptonic signal and vice versa.

### 2.5.1 Static Cuts

The cuts in this chapter have been inspired by one of the benchmark physics processes of charged Higgs bosons for the proposed Compact Linear Collider (CLIC) [37], even though this study is for a collision energy of  $\sqrt{s} = 1$  TeV. The cuts are shown in table 2.4 (2.5) for optimization for hadronic (semi-leptonic) signal significance and in table 2.6 (2.7) for optimization for correctly paired hadronic (semi-leptonic) signal significance.

In the following the cuts will be briefly explained.

- **(no) IsoLep** is the isolated lepton criteria as described in chapter 2.2

- **4 highest b-tags** is the sum of the highest four b-tag values in the event. (see chapter 2.3.2)
- $E_{\text{vis}}$  is defined as  $E_{\text{vis}} = \sum_{i=1}^{N_{\text{PFO}}} E_i$  where  $N_{\text{PFO}}$  is the number of tracks in the event after beam background reduction and  $E_i$  is the reconstructed energy of track  $i$ . In case of the semi-leptonic mode the energy of the lepton is added as well to  $E_{\text{vis}}$ .
- $\chi_{\text{H}\pm}$  is the first term of the  $\chi^2$  used for jet pairing in equation 2.1

$$\chi_{\text{H}\pm} = \left| \frac{(m_{j_1 j_2 j_3 j_4})^2 - (m_{j_5 j_6 j_7 j_8})^2}{2\sigma_{\text{H}\pm}^2} \right|$$

- $\chi_{\text{t}}$  is the top quark related term of the  $\chi^2$  used for jet pairing in equation 2.1

$$\chi_{\text{t}} = \left( \frac{m_{j_2 j_3 j_4} - m_{\text{t}}}{\sigma_{\text{t}}} \right)^2 + \left( \frac{m_{j_6 j_7 j_8} - m_{\text{t}}}{\sigma_{\text{t}}} \right)^2$$

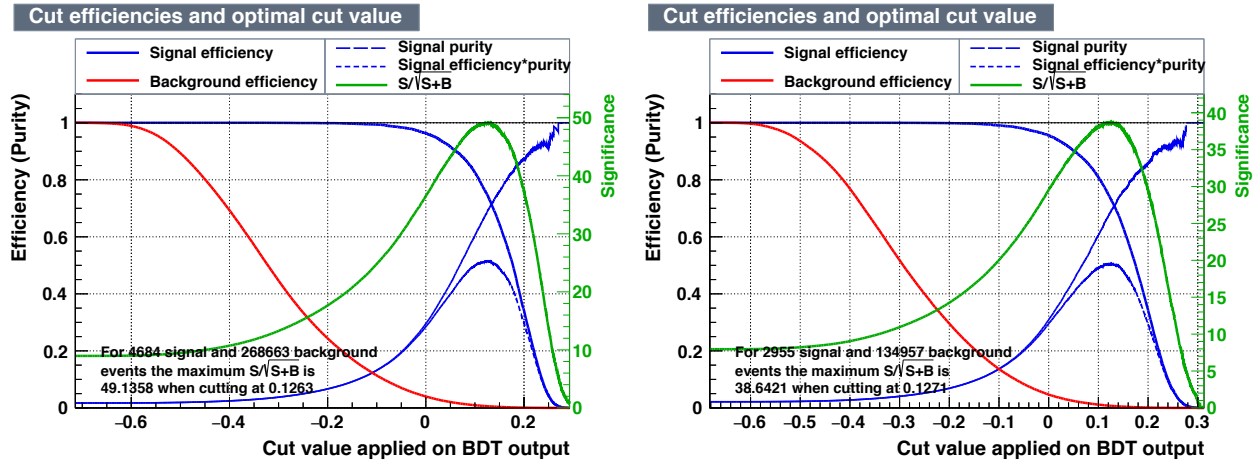

- $y_{n(n+1)}$  is provided by the LCFIplus package and obtained by the Durham algorithm which is briefly explained in chapter A.1.  $y_{n(n+1)}$  is the  $y_{\text{cut}}$  value at the transition of  $n + 1$  to  $n$  requested jets.
- **Thrust cuts:** MinorThrust, PrincipleThrust and cosThrustAxis are provided by the ThrustReconstruction processor of MarlinReco. They are variables of the event shape or in other words the distribution of momentum in the space.
- $m_{\text{miss}}$  is the missing mass in the event.

$$m_{\text{miss}} = \sqrt{(p_{\nu, \text{MEM}})^2}$$

$p_{\nu, \text{MEM}}$  was defined in equation 2.2

## 2.5.2 Boosted Decision Trees

The TMVA from ROOT was used to develop an alternative event selection. The boosted decision trees (BDT) and Boosted Decision Trees with gradient boosting (BDTG) were found to be the best methods for this purpose. In order to replace the event selection with static cuts, very similar input values as the cut values from the previous chapter were used. Small changes were made for “4 highest b-tags” and  $\chi_{\text{t}}$ . “4 highest b-tags” was divided in two highest b-tags and next two highest b-tags.  $\chi_{\text{t}}$  was divided into its summands. As a preselection the “No IsoLep” criteria was used in the hadronic mode and “IsoLep” was used for semi-leptonic mode. BDT was found to be the best method. The results are shown in figure 2.6.

**Figure 2.6:** Results of primary BDT event selection for hadronic (left) and semi-leptonic signal (right)

After the event selection with static cuts, there are two main types of remaining background; events with the same final state as the signal and top pair production (see table 2.10). Also two events of Z bosons decaying into a quark pair (marked as “Z(ha)” in table 2.10) are selected. These events have high cross section but only a relatively small number of generated events were available for this analysis. Top pair production ( $t\bar{t}$ ) has a similar event shape as signal and relative high cross section. Events with same final state are top pair production with a radiating SM Higgs ( $t\bar{t}h$  (sl/h)), top pair production with radiation Z boson ( $t\bar{t}Z$ ) and top pair production accompanied by a hard gluon ( $t\bar{t}b\bar{b}$ ). These events are very similar to the signal in number of jets, number of b-jets, event shape and so forth. However, the kinematics of these events are different. For example, the invariant mass of the bottom quarks, not coming from top, is peaking at Z mass and Higgs mass for  $t\bar{t}Z$  and  $t\bar{t}h$  respectively. The signal however is not peaking. Event selection with BDT is advantageous in such cases.

Therefore, a secondary background suppression was trained after applying the static cuts from chapter 2.5.1. The input values were chosen to separate same final state signal.

- Invariant mass and cosine of the decay angle from
  - Bottom quarks system
  - Top quarks system
  - Higgs bosons system
- Thrust information, namely:
  - PrincipleThrust
  - MajorThrust
  - MinorThrust
  - CosThrustAxis

- $y_{34}$
- $E_{\text{vis}}$
- Energy of the top quarks
- Number of charged tracks in the event
- $\chi^2$  (as defined in equation 2.1)
- Third and fourth highest b-tag
- $m_{\text{miss,t}}$
- Difference of momenta of bottom quarks
- Difference of momenta of Higgs bosons

For this secondary event selection, BDTG showed an advantage over BDT. However, training and applying to improve the signal significance does not show a relevant effect over the primary selection with BDT. On the other hand, training and applying it on correctly paired signal significance shows an effect. The results are shown in figure 2.7. The main reason for this behavior is probably the large fraction of mis-clustered and mis-paired signal and the indistinguishability of this signal and background with same final state.

**Figure 2.7:** Results of secondary BDTG event selection for hadronic (left) and semi-leptonic signal (right) trained for correctly paired signal

The output of primary BDT and secondary BDTG event selection are combined with the previous ROOT-file from the Marlin analysis. After that the best cut values are selected. The corresponding cuts are shown in table 2.8 for hadronic and in table 2.9 for semi-leptonic mode. The optimal cut values can be taken from figure 2.6, when optimizing for signal significance.

	had. signal	semi-l. signal	BG	Signif.	Effi.	Purity

## 2.6 Mass measurement

In order to develop a procedure for a possible mass measurement of the charged Higgs bosons, data samples with varied mass were generated. In order to know which margin the samples should be generated, the mass distribution of correctly paired signal was fitted with a Breit-Wigner distribution. The events with failed pairing and the background was fitted with one Gaussian distribution. The two shapes were added and fitted together. The uncertainty on the mean of the Breit-Wigner distribution, given by the used RooFit package [38] was about 1 GeV. With this very preliminary result, it was decided to produce five data sets in 2 GeV steps. In the further study, the correlation between fitted means and generated mass was difficult to evaluate. That is the reason why two additional data sets at  $\pm 10$  GeV were generated (see table A.1). The distribution of the invariant mass of the two reconstructed Higgs bosons of these seven samples is referred to as templates. For  $m_{H^\pm} = 350$  GeV, twice as many events were generated to provide a statistically independent test data set in addition to the template at this mass. The test data set contains just the number of events from each sample, so that some of the events in the large sample remained unused.

In the following, the charged Higgs mass distribution will be the invariant mass of the first four jets  $j_1$  to  $j_4$  and last four jets  $j_5$  to  $j_8$  from chapter 2.3.3. Both invariant masses are added to the same histogram. Hadronic and semi-leptonic signal are both added to this histogram as well.

The SM background which cannot be rejected by the event selection (chapter 2.5) is parameterized by a bifurcated Gaussian distribution (see figure 2.8). A bifurcated Gaussian is defined as

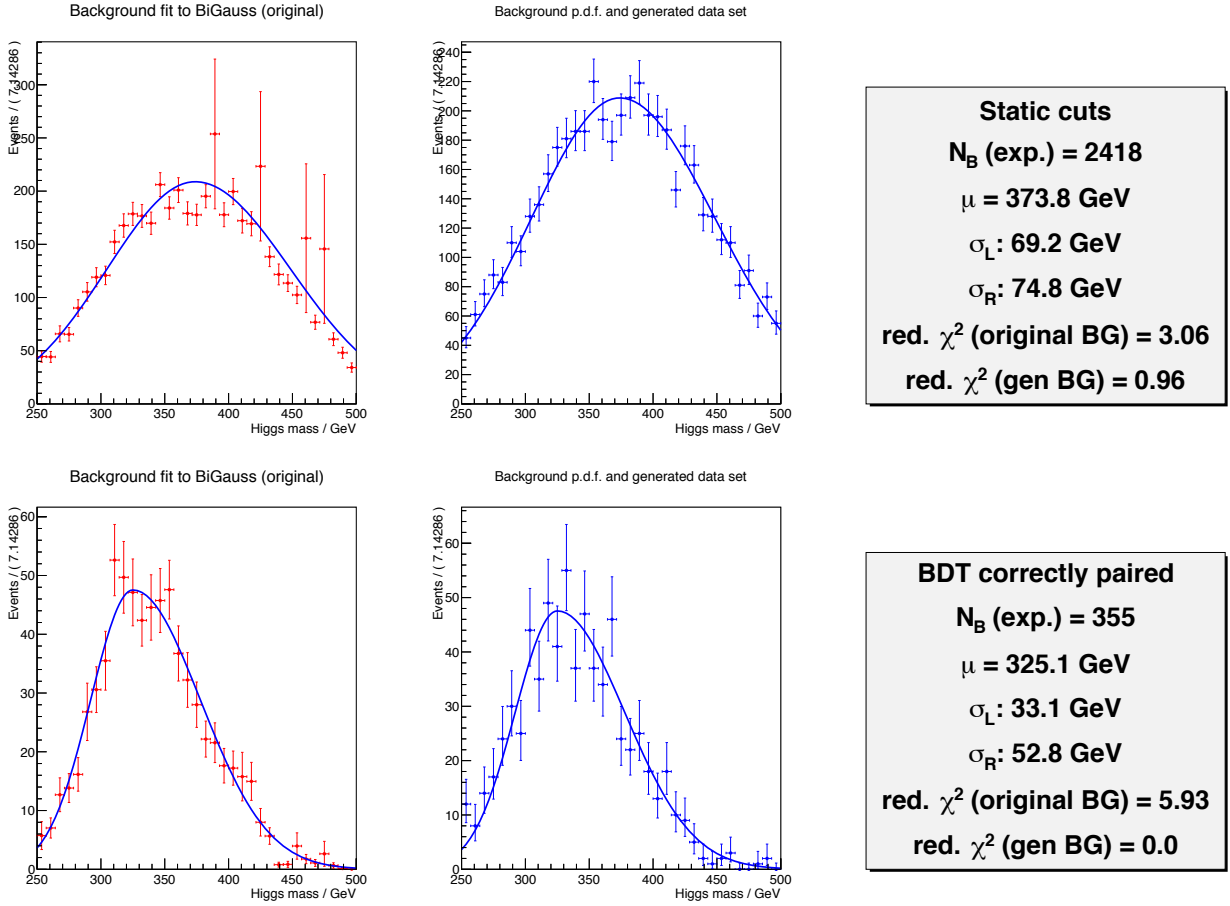

$$f(x) = \frac{1}{(\sigma_L + \sigma_R)\sqrt{\frac{\pi}{2}}} \exp\left[-\frac{1}{2}\left(\frac{x - \mu}{\sigma}\right)^2\right] \text{ with } \sigma = \begin{cases} \sigma_L & x - \mu < 0 \\ \sigma_R & \text{otherwise} \end{cases} \quad (2.4)$$

where  $\mu$  is the maximum<sup>4</sup> of the distribution and  $\sigma_L$  and  $\sigma_R$  are the widths of the left and right Gaussian respectively.

This parameterizing is necessary because the different data samples have different statistics and most samples have no additional statistic to provide an independent test data set. For example the data samples of Z boson to two quarks decay have very low statistics. Therefore they have to be weighted with 69.4 (see table A.1). Only two event are selected by the static cuts, which results in four bins with large error bars in figure 2.8. Nevertheless, it is assumed that the number of events (even with large uncertainty) is an appropriate approximation. However, for the purpose of getting a realistic distribution in the reconstructed Higgs mass a bifurcated Gaussian was chosen because it seems to fit well even if there is a slight change in the event selection.

---

<sup>4</sup> $\mu$  is sometimes referred to as mean but this is only true if  $\sigma_L = \sigma_R$

**Figure 2.8:** Charged Higgs mass distribution of SM background; upper plots show the background with static cut selection optimized on signal significance (chapter 2.5.1) and lower shows BDT based selection optimized on correctly paired signal significance (chapter 2.5.2). Left hand plots reveal the original distribution and the fitted bifurcated Gaussian; the right hand plot corresponds to the generated distribution which is used for the further mass determination is shown. Information of the fit is given on the right.

## 2.6.1 Template method

For the template method a test set is compared to the templates (see figure 2.9). In order to compare the distributions, the minimum chi squared method is used. Here  $\chi_{\text{temp}}^2$  is used as an observable for the difference of the distributions with the following definition

$$\chi_{\text{temp}}^2 = \sum_{i=0}^N \frac{(T_i - S_i)^2}{S_i}$$

where  $N$  is the number of bins  $T_i$  accounts for the expected number of events in bin  $i$  originate from the template;  $S_i$  is the corresponding number of events in bin  $i$  of the test set. The templates as well as the test data set includes the SM background as discussed before. All templates contain the same generated background set but the background set of the test sample is generated independently. The number of background events for the templates is fixed as

**Figure 2.9:** Template fit of varied  $m_{H^\pm}$ ; in blue histograms of templates and black data points from a test data set with  $m_{H^\pm} = 350$  GeV; the event selection is done by BDT optimized on correct pairing

the expected number from chapter 2.5. However, the corresponding number for the test set is a random number from a Poisson distribution with mean of the expected number.

The obtained  $\chi_{\text{temp}}^2$  values from the seven templates are plotted on the corresponding generated Higgs mass (see figure 2.10). In the case where the templates have the same statistics as the test data set the uncertainty on  $\chi_{\text{temp}}^2$  would be  $\Delta\chi_{\text{temp}}^2 = \sqrt{2N}$ , where  $N$  is the number of bins. Here, the template size is about twice of the test data size. Since the function of  $\chi_{\text{temp}}^2$  is unknown,  $\Delta\chi_{\text{temp}}^2 = \sqrt{2N}$  is used as rough estimate, which is only a visual orientation and has no influence on the final result.

The  $\chi_{\text{temp}}^2$  points in figure 2.10 are fitted with a parabola where the minimum is the estimate of the real experiment for the final result of the mass measurement. Therefore

$$m_{H^\pm} = \chi_{\text{inv}}^2(\chi_{\text{min}}^2) \quad \text{with} \quad \left[ \frac{d\chi_{\text{temp}}^2(x)}{dx} = 0 \right]_{x=\chi_{\text{min}}^2}$$

where  $\chi^2(x)$  is the fitted function and  $\chi_{\text{inv}}^2(x)$  the inverse. The statistical uncertainty is given as

$$\Delta m_{H^\pm} = \chi_{\text{inv}}^2(\chi_{\text{min}}^2 + 1 > m_{H^\pm}) - \chi_{\text{inv}}^2(\chi_{\text{min}}^2 + 1 < m_{H^\pm})$$

**Figure 2.10:**  $\chi^2_{\text{temp}}$  obtained from the comparison of the templates and a test data set fitted by a parabola; the event selection is done by BDT optimized on correct pairing

## 2.6.2 Shape method

In this method, the aim is to identify the signal shape and perform a fit of its maximum. Then a linear regression is applied to the maximum of the signal shape and the generated mass of the templates. From this information and the maximum of the test data set, the underlying mass is reconstructed.

The signal shape is approximated with two bifurcated Gaussian distributions (equation 2.4); a narrow one for correctly paired signal and a wide one for wrong paired signal. Correctly paired signal is selected as defined in chapter 2.3.3 and fitted with a bifurcated Gaussian and a normal Gaussian (left column of figure 2.11). Signal, where the clustering has failed (definition in chapter 2.3.1), is fitted to the bifurcated Gaussian for wrong pairing. This is displayed in the second column of figure 2.11. These two preliminary fits fulfill only the purpose of gaining reliable starting values for fitting the total signal shape. Then both bifurcated Gaussian distributions are fitted to the signal shape. This is shown in the right half of figure 2.11. No generator information is needed for this procedure. It can be done the same way with real data.

For the next step a generated background data set is added to templates and test data set in the same manner as explained before for the template method. Then all seven templates are fitted with three bifurcated Gaussian distributions for background, correctly and wrong paired signal. All parameters are fixed to the expected value except the maximum of correctly and

**Figure 2.11:** Charged Higgs mass distribution for signal and shape fitting; upper plots show the background with static cut selection optimized on signal significance (chapter 2.5.1) and lower shows BDT based selection optimized on correctly paired signal significance (chapter 2.5.2). The first two columns show the preliminary fits to obtain start values for the final fit. The third column reveals the final fit where correctly paired (dashed blue) and wrong paired signal (dashed red) is fitted with bifurcated Gaussian distributions. In the left column information to the fit is shown.

wrong paired distributions which will be called  $\mu_c$  and  $\mu_w$  respectively in the following. The linear regression of the results for  $\mu_c$  and  $\mu_w$  and the generated mass are shown in figure 2.12.

The test data set is fitted in the same manner. This fit is shown for the four different event selections in figure 2.13. From this, the estimate for shape method of the real experiment for the final result is given by

$$m_{H^\pm} = b\mu + a$$

**Figure 2.12:** Linear regression of the generated mass to the maximum  $\mu$  of the correctly paired (wrong paired) bifurcated Gaussian in the left (right) figures; upper plots show the background with static cut selection optimized on signal significance (chapter 2.5.1) and lower shows BDT based selection optimized on correctly paired signal significance (chapter 2.5.2). On the left side information to the fit and the results for  $m_{H^\pm}$  are shown.

where  $b$  is the slope of the linear regression and  $a$  is the y-axis intercept. Therefore the uncertainty is given by

$$\begin{aligned} \Delta m_{H^\pm} &= \sqrt{\left(\frac{\Delta\mu}{b}\right)^2 + \left(\frac{\Delta a}{b}\right)^2 + (\mu\Delta b)^2} \\ &= \sqrt{\Delta_{\text{fit}}^2 + \Delta_{\text{const}}^2 + \Delta_{\text{linear}}^2} \end{aligned}$$

In figure 2.12 the results from the test data set is shown in blue color.

The two results from wrong and correctly paired signal are two independent observables. The correlation is neglected for now. Therefore, the two results can be combined to one by weighted

**Figure 2.13:** Fit of test data set by the shape method for different event selections as denote each figure; the data points is the test data set; the black function the total function, solid blue - total signal, dashed blue - wrong pairing, green - correct pairing and red is the background

average.

$$m_{a,H^\pm} = \frac{w_c m_{c,H^\pm} + w_w m_{w,H^\pm}}{w_c + w_w} \quad \text{with} \quad w_i = \frac{1}{(\Delta m_{i,H^\pm})^2}$$

Hence, the uncertainty is

$$\Delta m_{a,H^\pm} = \frac{1}{\sqrt{w_c + w_w}}$$

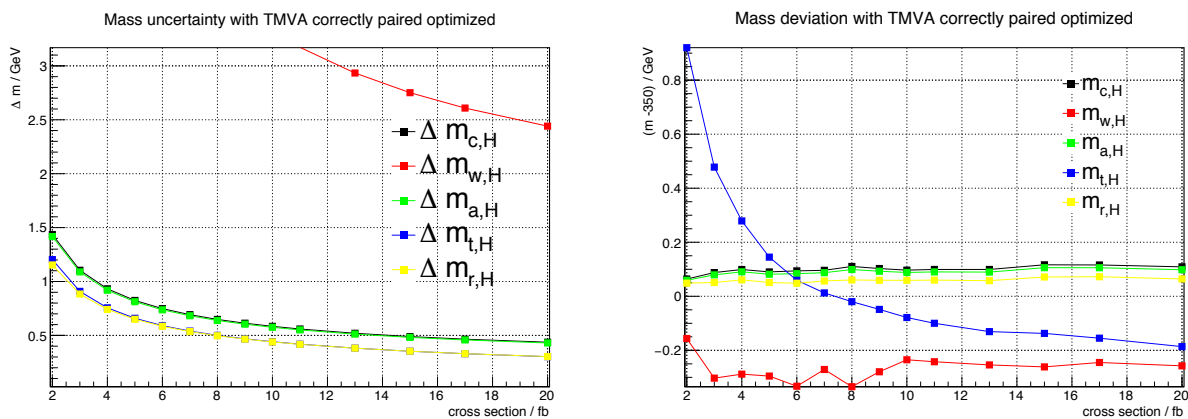

However, since  $\Delta m_{c,H^\pm} \ll \Delta m_{w,H^\pm}$  the advantage of the weighted average over the value estimated from the position of the correctly paired distribution is minimal (see 2.14).

### 2.6.3 Reduced shape method

This method is a variation of the shape method. Rather than combining two results as for  $m_{a,H^\pm}$ , the fit can be reduced to only one variable, since the relations of  $m_{H^\pm}(\mu_c)$  and  $m_{H^\pm}(\mu_w)$  is known. RooFit provides a `RooFormulaVar` object enables the connection of fitting parameters with a formula. Connecting two of these objects with the formula, gained from the linear regressions, reduces the fit parameter to one which is directly the result of the estimate of the charged Higgs mass. The result is shown as  $m_{r,H^\pm}$  for the examples in figure 2.12.

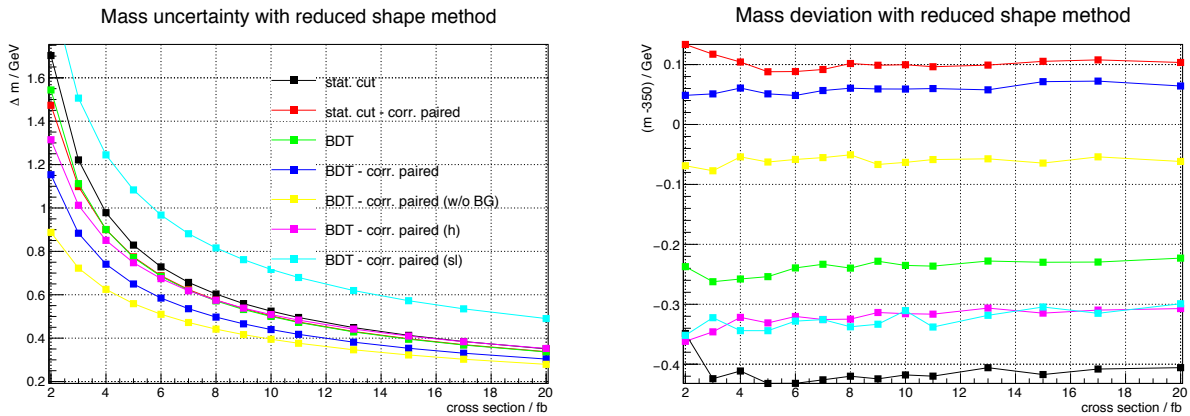

In order to test the three methods described above, as well as the different event selections described in chapter 2.5, a Monte Carlo toy study was performed. Therefore a second independent template was taken from the second half of the data samples with  $m_{H^\pm} = 350$  GeV. On the basis of this template 10,000 toy Monte Carlo test data sets are generated. The same procedures for the mass measurement is repeated on these samples. The number of signal events in the toy test data set can be varied and related to a cross section while the number of background events is constant.

The uncertainty and deviation from expected value of all mass measurement methods with the BDT based selection optimized on correctly paired signal significance (chapter 2.5.2) is shown in figure 2.14. In figure 2.15 (figure 2.17 / figure 2.16) uncertainty and deviation of reduced shape method (template method / shape method) is shown with different event selections.

**Figure 2.14:** Mass uncertainty (right) and mass deviation of the expected value (left) for different mass measurement methods as noted in the legend; using the BDT based event selection optimized for correctly paired signal

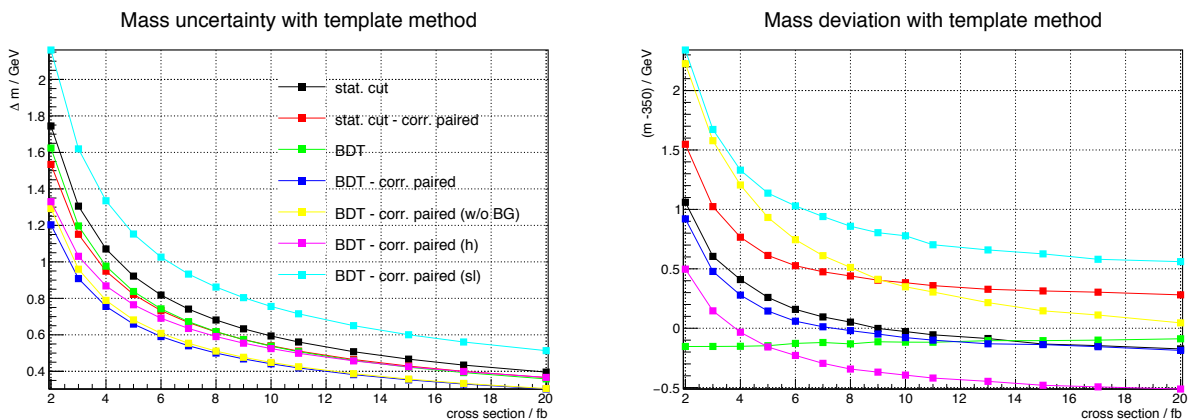

With the result from figure 2.14, it is shown that the uncertainty from the template method and reduced shape method are the lowest. But the deviation of the template method is depended

**Figure 2.15:** Mass uncertainty (right) and mass deviation of the expected value (left) from the reduced shape method for different event selections as noted in the legend

**Figure 2.16:** Mass uncertainty (right) and mass deviation of the expected value (left) from the shape method estimated from the position of the correctly paired distribution for different event selections as noted in the legend

**Figure 2.17:** Mass uncertainty (right) and mass deviation of the expected value (left) from the template method for different event selections as noted in the legend

on the cross section. This is unexpected but the reason could be that the true function of  $\chi_{\text{temp}}^2$  is not parabolic. If the true shape is asymmetric and has a steeper slope on one side, it could let the average result for the toy study deviate to the side of gentler slope. A different explanation could be that the fraction of signal and background is different between test data set and templates. However, it has been made sure that apart from the Poisson fluctuation in the test data set, there is no difference in the composition. Moreover, the result for the toy Monte Carlo study without background is dependent on the cross section as well (see figure 2.17).

In figures 2.15, 2.16 and 2.17 the uncertainty is the lowest for the event selection optimized for correctly paired signal based on BDT. Only the same selection fitted without background is better. In the case of static cuts, it is advantageous as well to optimize the cuts for correctly paired signal.

The deviation is generally smaller than the statistical uncertainty, so the results are reliable but the deviation for template method needs to be corrected or/and taken into account as systematic uncertainty.

# 3 Discussion

## 3.1 Result

For the neutrino reconstruction the Missing Momentum Method showed the best performance. However, the Missing Transversal Momentum Method has shown a good potential and might be useful for studies where very high precision of the neutrino reconstruction is necessary.

The event selection has been conducted with static cuts as well as with the multivariate analysis toolkit from ROOT using boosted decision trees (BDT). The selection was optimized on signal significance or on correctly paired signal significance. An overview of the observed significances, efficiencies, purities and mass precision of the event selection can be found in table 3.1.

Cut type	Optim. type	Mode	Significance	Efficiency	Purity	mass precision
Static cuts		hadronic	44.61	65 %	64 %	0.56 GeV
Static cuts		semi-lep.	36.51	43 %	67 %	
Static cuts	corr. paired	hadronic	21.86	62 %	66 %	0.54 GeV
Static cuts	corr. paired	semi-lep.	19.04	55 %	63 %	
BDT		hadronic	49.14	73 %	67 %	0.53 GeV
BDT		semi-lep.	38.64	46 %	71 %	
BDT	corr. paired	hadronic	26.63	74 %	82 %	0.47 GeV
BDT	corr. paired	semi-lep.	22.99	64 %	79 %	

**Table 3.1:** Summary of significances, efficiencies, purities and mass precision with reduced shape method for 9 fb for the corresponding event selection

For the measurement of the charged Higgs mass, three methods have been conducted. The best method was shown to be the reduced shape method with the BDT based event selection optimized on correctly paired signal significance. This configuration was found to have a statistical uncertainty of 0.5 GeV assuming the cross section of  $H^\pm$  pair production to be 9 fb and the branching ratio  $BR(H^\pm \rightarrow tb) = 90\%$ . This relates to a relative uncertainty of 0.14 %.

## 3.2 Outlook

With the parameter set used in this analysis the Minimal Supersymmetric Standard Model (MSSM) is excluded. However, it is not necessary to assume the MSSM for the event genera-

tion, as long as the mass, width and charge of the charged Higgs boson is fixed. All underlying probability density function for Monte Carlo simulation are fixed in this process. This makes this study transferable to a wide range of Two Higgs Doublet Models. The mass has been fixed in this study but if there is a discovery of a charged Higgs-like particle the techniques and even the developed analysis program can be adjusted to the discovery.

There are open questions in this analysis. It has to be investigated why the deviation of the mean of result for the template method from toy Monte Carlo study depends on the cross section. Therefore, it is necessary to produce more mass samples in a smaller margin, to study the underlying  $\chi^2$  minimization. At this point, the template method is unstable and should not be used.

In this study the following possible sources of systematic uncertainty are not discussed. However, they are expected to be small, compared to the statistical uncertainty.

- Beam energy
- Beam polarization
- Luminosity
- Jet energy calibration
- Unexpected background
- Beam-induced-background and its removal

In this analysis it was assumed that the simulation is in agreement with the real events. This assumption is needed to be able to compare the test data set, which will be real data in the ILC experiment, to the templates, which will be simulated. However, the simulation at this point will not be in total agreement with what will be seen at the ILC. Nevertheless, when this analysis is conducted, the ILC project will be running for several years and simulation will evolve with the project. Furthermore, the deviation of the nature and the simulation will be known from other measurements. An example is the beam background. At this point it is unknown, whether the real events and simulation behaves under beam background removal with kt-algorithm described in chapter 2.3.1 the same or not. However, at the point this analysis will be conducted with real data, similar background removal will be used for other analyses such as top pair production or top Yukawa studies. With this experience, the influence can be corrected or/and the resulting systematic uncertainty will be better understood. The same can be said about the mass measurement, including the background estimation in it, and the neutrino reconstruction.

There are a number of SM backgrounds, that have low statistics (see table A.1). All available samples were used. However, in order to have a reliable result for the event selection based on BDTs, generated events worth one experiment are needed of training and testing each. The

low number of generated events can result in over training.

However, Monte Carlo simulation and the Standard Model predictions are in impressive agreement with nature from what we know from LHC and other experiments.

In addition, it would be interesting to see the influence of using the Missing Transversal Momentum Method instead of the Missing Momentum Method for neutrino reconstruction on the final result, as well as the influence of the discussed jet pairing optimization. Nevertheless, the influence is expected to be minor.

Even though the decay rate asymmetry may be very small at the charged Higgs mass studied here [12], it could be interesting to estimate the precision of  $\delta_{f\bar{f}'}^{CP}$  defined in chapter 1.2.

The event selection is optimized for a  $H^\pm$  pair production of 9 fb and  $BR(H^\pm \rightarrow tb) = 90\%$ . For a different ratio of background and signal, the event selection is not optimal.

There are earlier studies of charged Higgs Bosons at linear colliders [11][37][39]. However, the conditions and collision energies were different. Nevertheless, a study with TESLA conditions and a charged Higgs boson mass of 300 GeV at a collision energy of  $\sqrt{s} = 800$  GeV was conducted [39]. The result of the study is a mass uncertainty of 1.1 GeV by reconstructing the hadronic channel only. The number of events assumed in that study would correspond to about 6 fb in this study where an uncertainty by analyzing only hadronic signal would result in a mass uncertainty of 0.8 GeV. Whether these two studies are comparable is however questionable. Nonetheless, a kinematic fit is being used to improve the statistical uncertainty which could be applied to this study as well. In this study only Standard Model background has been considered. In a similar study on charge Higgs boson at Linear colliders [11], it has been found that the SUSY background from heavy neutral Higgs bosons  $AH \rightarrow bbbb$  is peaking in the same region. Since their mass may (depending on the model) change in correlation with the charge Higgs mass and that way have major influence on the final result. In case of MSSM the mass of the charged Higgs boson is very similar to the mass of A and H. This would let the cross section of  $AH \rightarrow tttt$  peak at the used parameter set and would become the major background.

# A Appendix

## A.1 Durham algorithm

The Durham [35] algorithm works in the following manner.[40]

1. Calculate the distance of tracks  $v_{ij} = 2(1 - \cos \theta_{ij})$
2. Find smallest  $v_{ij}$
3. Calculate  $y_{ij} = \min(E_i, E_j)v_{ij}$ 
  - a) If  $y_{ij} < y_{\text{cut}}$  merge the two tracks - update all values for  $v_{ij}$  and start over with step 2
  - b) If  $y_{ij} > y_{\text{cut}}$  return to step 2 and look for next larger  $v_{ij}$
4. If there are no tracks left to merge and there are more tracks than requested jets raise  $y_{\text{cut}}$  and go to step 2

**Figure A.1:** Charged Higgs mass (right:  $m_{H^+}$ , left:  $m_{H^-}$ ) in green  $\gamma\gamma$ -background removed by generator in formation, black without any correction and other colors with corrected with kt-algorithm with varied  $R$  (see legend)
